

Q1 > Fight Duration Over Time

The series shows a clear upward drift in fight duration across the 2016-2026 window. The non-title median starts at 4.5 minutes in 2016, climbs to roughly 7-8 minutes in 2017-2020, and reaches 10-14 minutes in 2021-2026. This is one of the more visually pronounced trends in the data, with the median nearly tripling over a ten-year span. The mean tracks the median closely throughout the period, confirming the shift is structural rather than driven by outliers.

Title fights (red dashed line, $n = 70$ across 10 years) sit far above the non-title series, with multiple years reaching the 25-minute regulation ceiling (2019, 2020, 2024, 2025). Title bouts at this promotion routinely go the full distance, which pushes the median to the cap. With an average of 7 title fights per year, the title series is less volatile than at promotions with sparser championship calendars, but individual years still oscillate widely between 9 and 25 minutes.

The combined picture is of a promotion that started in a finish-heavy regional phase and has rapidly converged toward a longer-duration profile, with title fights leading and non-title fights following.

Q2 > Outcome Distribution Over Time

Year-by-year visual composition tracks the shift clearly. The early period (2016-2019) is finish-dominated: KO/TKO accounts for 46-57% of decisive fights, submissions for 20-35%, and decisions for 7-26%. From 2020 onward, decisions climb sharply into the 28-49% range while submissions compress to roughly 15-22%. KO/TKO remains substantial across the entire series, sitting in the 29-51% range without a clear directional drift. The pattern is consistent with promotional maturation: as the roster developed from early regional contracts into a more established competitive pool, matchups have produced fewer one-sided finishes and more time-limit outcomes. The KO/TKO baseline staying high (above 30% throughout the recent years) indicates that striking remains a primary finishing tool even as decisions become more common.

Q3 > Mean Height by Weight Class

The ordinal progression is clean and well-behaved across all ten classes, with a proper gap between Heavyweight (190.1 cm, n = 80) and Light Heavyweight (188.9 cm, n = 150). The 1.2 cm separation at the top is in the expected range for adjacent divisions and indicates that the Heavyweight class has access to a real 190+ cm fighter pool rather than topping out at the Light Heavyweight ceiling.

The absolute height levels are at the upper end of what is typically observed in regional MMA rosters. This is a demographic effect: Czech, German, and broader Central European populations sit among the tallest in the world. Czech adult male mean stature is approximately 180-181 cm and German is approximately 179-180 cm, against a global mean closer to 171-173 cm. This baseline difference propagates into every weight class on the roster. The Heavyweight mean at 190.1 cm sits at the top of the data, and the middle divisions (Middleweight 183.5, Welterweight 181.2) reflect a roster whose physical baseline is structurally taller than rosters drawn from East Asian, Latin American, or globally mixed pools.

The Catchweight bucket (178.6 cm, n = 268) is one of the larger categories in the dataset and has the highest within-class standard deviation (6.87 cm vs 4 to 5 cm in the standard divisions). Catchweight is used extensively as a matchmaking instrument rather than as an exception, and the bucket aggregates fighters across a wide weight range. The mean lands just below Lightweight, which reflects the central tendency of the matched weights but masks an underlying multimodal distribution.

Flyweight (n = 44) and Strawweight (n = 35) sit at the lower end of the sample-size range and should be read with wider implicit confidence intervals than the larger divisions.

Q4 > Win Rate by Height Advantage

Lightweight is the only division to reach statistical significance after correction for multiple comparisons. In this class, the taller fighter wins 62.8% of analyzed bouts (n = 121), and the 95% confidence interval sits entirely above the 50% baseline. The height advantage in Lightweight is therefore a real effect and cannot be attributed to sampling noise.

Welterweight falls just below the corrected threshold, with a win rate of 59.8% (n = 117). Since the sample size is virtually identical to Lightweight, the difference in significance between the two classes comes from effect magnitude, not statistical power. Even so, the direction of the signal is the same, both favor the taller fighter.

In the remaining divisions, the directional pattern holds but with smaller magnitudes. Light Heavyweight, Catchweight, and Bantamweight sit above the baseline without reaching significance. Middleweight and Featherweight approach a statistical tie. The only reversed result is Heavyweight, where the shorter fighter wins slightly more often (46.9%, n = 32). This reversal is most likely a small-sample effect: with only 32 fights, the confidence interval is wide enough to include both the baseline and substantial positive values. For comparison purposes, equivalent analysis on the UFC dataset returns 53.4% in the same division, opposite direction, but also not significant after BH correction. The reversal between the two organizations is consistent with sampling fluctuation on both sides.

The Catchweight result (55.7%, n = 97) should be discounted on structural grounds. Since the category groups pairs of fighters with variable weight differences, the height comparison is contaminated by the weight asymmetry between opponents, and the effect cannot be interpreted as advantage conditional on weight.

Strawweight and Flyweight were excluded from the test due to insufficient sample after restricting to fights with both heights recorded.

When several statistical tests are conducted simultaneously, the chance that one of them returns a "positive" result purely by chance — without any real underlying effect, increases. It is similar to tossing a coin many times: the more tosses, the higher the chance of an unusual sequence appearing simply by luck.

The Benjamini-Hochberg correction, abbreviated as BH in the charts, adjusts the results to avoid this problem. It makes the approval criterion progressively stricter as the number of tests grows, so that only genuinely strong effects remain classified as significant.

In this study, eight weight classes were tested simultaneously. Before correction, three classes appeared to show a statistical advantage for the taller fighter. After correction, only Lightweight survived, indicating that this is the only result robust enough not to be explained by chance. In other words, in the Lightweight division of the analyzed organization, the taller fighter holds a statistically significant advantage in winning.
